

# Word Hy-phen-a-tion By Com-pu-ter

Philip L. Bewig  
pbewig@gmail.com  
April 24, 2009

In 1982, Frank Liang published in his doctoral dissertation *Word Hy-phen-a-tion By Com-pu-ter* a description of the hyphenation algorithm that he invented for Donald Knuth's TeX typesetting program; his algorithm is the basis of most of the hyphenation programs used today. Liang's algorithm is described in Appendix H of *The TeXbook* by Knuth. Liang's algorithm never inserts a hyphen where one does not belong, but does miss some opportunities to insert hyphens where they do belong; Liang claims to find 95% of the hyphens in most texts. Liang's algorithm is quick, and reasonably stingy with space.

Liang's method works by pre-computing a list of hyphenating and inhibiting patterns based on a hyphenation dictionary. First, a list of hyphenating patterns is established; for instance, `-tion` and `c-c` are good hyphenating patterns. But all hyphenating patterns have exceptions; for instance, the `-tion` pattern improperly hyphenates the word `cat-ion`. Thus, a set of inhibiting patterns prevents hyphenations; in this case, the inhibition pattern `.ca=t` (the dot indicates the beginning or end of a word, the equal-sign inhibits a hyphen) overrides the hyphenation pattern and prevents the hyphen at `ca-tion`. Of course, there are exceptions to the inhibition patterns; Liang's algorithm goes five levels deep — hyphenation, inhibition, hyphenation, inhibition, hyphenation — to get a good set of patterns, and even then requires an exception listing to fix a few words that would otherwise be hyphenated incorrectly. It is also required that a word must have a least five letters to be hyphenated, no hyphens can be inserted after the first letter or before the last letter of a word, and any word that includes non-alphabetic characters is never hyphenated.

Consider this example of hyphenating the word `hyphenation`: there are two hyphenating patterns `1na` and `1tio`, then three inhibiting patterns `n2at`, `2io`, and `he2n`, then another hyphenating pattern `hy3ph`, another inhibiting pattern `hena4`, and finally another hyphenating pattern `hen5at`:

```
. h y p h e n a t i o n .
    1n a
        1t i o
            n2a t
                2i o
                    h e2n
                    h y3p h
                        h e n a4
                        h e n5a t
.0h0y3p0h0e2n5a4t2i0o0n0.
    h y-p h e n-a t i o n
```

After all the patterns present in the word are identified, the highest number at any inter-letter position wins (we'll call that number a *rule*), and hyphens are inserted at all the odd-numbered rules. In this case, the `1na` pattern originally placed a hyphen at `hyphenation`, but the `he2n`

pattern inhibited the hyphen, because rule 2 trumps rule 1; likewise, `hena4` inhibited `1tio`. Note that three patterns start at the fourth letter of hyphenation: `he2n`, `hena4`, and `hen5at`.

Liang's hyphenation algorithm iterates through the letters of the input word, identifying all the patterns that are present in the word, and takes the maximum rule at each position. The task of identifying the patterns calls for some sort of search algorithm; Liang used a trie that he cleverly packed into an array.

Our implementation follows Liang's closely. Our tries are based on association lists, but instead of the standard Scheme association lists kept in random order, we use our own association lists, in which comparisons are case-insensitive and characters are stored in ascending order; `a-look` looks up the value associated with character `c` in a-list `a`, and `a-bind` establishes a binding of value `x` for character `c` in a-list `a` whether or not `c` is already present in `a`:

```
(define a-null '())

(define (a-look c a)
  (cond ((null? a) #f)
        ((char-ci<? c (caar a)) #f)
        ((char-ci<? (caar a) c) (a-look c (cdr a)))
        (else (car a)))

(define (a-bind c x a)
  (cond ((null? a) (list (cons c x)))
        ((char-ci<? c (caar a)) (cons (cons c x) a))
        ((char-ci<? (caar a) c) (cons (car a) (a-bind c x (cdr a))))
        (else (cons (cons c x) (cdr a))))
```

Following Chris Okasaki's implementation of tries in his textbook *Purely Functional Data Structures*, a trie is a pair consisting of a value and an a-list of successors. The value is boxed in a list, so '`()`' indicates no-value and '`(x)`' indicates the value `x`. The null trie conses the null list to the null a-list:

```
(define t-null (cons '() a-null))
```

Trie lookup goes one character at a time. There are two ways for lookup to fail: if the end of the key finds a '`()`' value, or if an intermediate node does not exist:

```
(define (t-look ks t)
  (if (null? ks)
      (if (pair? (car t)) (caar t) #f)
      (let ((x (a-look (car ks) (cdr t))))
        (if x (t-look (cdr ks) (cdr x)) #f))))
```

Adding or replacing a value in a trie is similar to lookup, except that it never fails; if necessary, the trie is extended with a null node:

```
(define (t-bind ks x t)
  (if (null? ks) (cons (list x) (cdr t))
      (let* ((al (a-look (car ks) (cdr t)))
             (t2 (t-bind (cdr ks) x (if (pair? al) (cdr al) t-null))))
        (cons (car t) (a-bind (car ks) t2 (cdr t))))))
```

We store the patterns and exceptions in lists (they are symbols, not strings, because that's how Liang's listing is given); the full lists are given below:

```
(define patterns '(.ach4 .ad4der .af1t ... zte4 4z1z2 z4zy))

(define exceptions '(as-so-ciate ... ta-ble))
```

Our first task is to split a pattern like hen5at into the key henat and rules 000500; note the use of `symbol->string`:

```
(define (split-pat pat)
  (let loop ((ps (string->list (symbol->string pat))) (cs '()) (ns '()))
    (cond ((null? ps)
            (if (= (length cs) (length ns))
                (values (reverse cs) (reverse (cons 0 ns)))
                (values (reverse cs) (reverse ns))))
           ((and (null? (cdr ps)) (char-numeric? (car ps)))
                (values (reverse cs)
                        (reverse (cons (- char->integer (car ps)) 48) ns))))
           ((not (char-numeric? (car ps)))
            (loop (cdr ps) (cons (car ps) cs) (cons 0 ns)))
           (else (loop (cddr ps)
                     (cons (cadr s) cs)
                     (cons (- (char->integer (car ps)) 48) ns)))))))
```

Exceptions are handled by making them un-exceptional: an exception like `ta-ble` is turned into a pattern like `6.6t6a7b6l6e6.6` and entered into the trie along with the regular patterns. Because 7 and 6 are greater than the other hyphenation and inhibition rules, and because the pattern is anchored with a dot at beginning and end, the exception rules will always trump any other rules that may exist in the word. Turning the exceptions into patterns means they don't have to be handled specially, so the program can be simpler. Here is the code to split an exception into pattern and key:

```
(define (split-exn exn)
  (let loop ((ps (append (list #\.) (string->list (symbol->string exn)) (list #\.)))
            (cs '()) (ns '()))
    (cond ((null? ps) (values (reverse cs) (reverse (cons 6 ns))))
          ((char=? (car ps) #\-)
           (loop (cddr ps) (cons (cadr ps) cs) (cons 7 ns)))
          (else (loop (cdr ps) (cons (car ps) cs) (cons 6 ns)))))))
```

`T-hyph` is the trie that stores all the key/rule pairs, built by looping through the lists of patterns and exceptions:

```
(define t-hyph
  (let loop ((pats patterns) (exns exceptions) (t t-null))
    (cond ((null? exns) t)
          ((null? pats)
           (call-with-values (lambda () (split-exn (car exns)))
                         (lambda (cs ns) (loop pats (cdr exns) (t-bind cs ns t)))))
           (else (call-with-values (lambda () (split-pat (car pats)))
                                 (lambda (cs ns) (loop (cdr pats) exns (t-bind cs ns t)))))))
```

The standard trie function `t-look` returns the single value associated with a key. We need instead to get a list of all the rules along the path from a substring; for instance, when examining

the substring `henation.`, we find the three patterns `he2n`, `hena4`, and `hen5at`. `t-looks` is similar to `t-look`, but returns a list, possibly null, instead of a single value:

```
(define (t-looks ks t)
  (if (null? ks)
      '()
      (if (pair? (car t)) (list (caar t)) '())
          (let ((x (a-look (car ks) (cdr t))))
            (if x
                (if (pair? (car t))
                    (cons (caar t) (t-looks (cdr ks) (cdr x)))
                    (t-looks (cdr ks) (cdr x)))
                (if (pair? (car t)) (list (caar t)) '()))))))
```

We are ready now to show the function that performs hyphenation. `Hyphenate` takes a single word, as a string, and returns a list of substrings between hyphenation points; for instance, `(hyphenate "hyphenation")` returns `("hy" "phen" "ation")`. After testing the length and looking for non-alphabetic characters, the outer loop iterates over the letters of the input word, surrounded by dots. The rules are stored in a two-part list, the part before the current letter and the part after the current letter. When the input word is exhausted, the substrings are collected in the first inner `let`. Otherwise, the `fold-left` in the second inner `let` saves the maximum rule at each position for each pattern returned by `t-looks`.

```
(define (hyphenate word)
  (let ((ws (string->list word)))
    (cond (((< (length ws) 5) (list word))
           ((any? (lambda (c) (not (char-alphabetic? c))) ws) (list word))
           (else (let loop ((ws (append (list #\.) ws (list #\.)))
                           (front (make-list (+ (length ws) 3) 0))
                           (back '()))
                  (if (null? ws)
                      (let loop ((cs (string->list word)) (hs (fixup back)) (p '()) (ps '()))
                        (cond ((null? (cdr hs)) (reverse (cons (list->string (reverse p)) ps)))
                              ((odd? (car hs))
                               (loop (cdr cs) (cdr hs) (list (car cs))
                                     (cons (list->string (reverse p)) ps)))
                              (else (loop (cdr cs) (cdr hs) (cons (car cs) p) ps))))
                      (let ((new-front (fold-left max-rule front (t-looks ws t-hyph))))
                        (loop (cdr ws) (cdr new-front) (cons (car new-front) back)))))))))))
```

`Hyphenate` calls two helper functions: `max-rule` is called by `fold-left` to loop through the rules for a particular pattern, saving only the maximum at each step, and `fixup` implements the requirement that a word cannot begin or end with a single-letter substring:

```
(define (max-rule xs ys)
  (let loop ((xs xs) (ys ys) (zs '()))
    (if (or (null? xs) (null? ys))
        (append (reverse zs) xs)
        (loop (cdr xs) (cdr ys) (cons (max (car xs) (car ys)) zs)))))

(define (fixup xs)
  (cons 0 (cons 0 (cdddr (reverse (cons 0 (cons 0 (cddr xs))))))))
```

`Fold-left`, `make-list` and `any?` come from a standard library:

```
(define (fold-left op base xs)
  (if (null? xs)
      base
      (fold-left op (op base (car xs)) (cdr xs))))
```

```
(define (make-list n x)
  (let loop ((n n) (xs '()))
    (if (zero? n) xs
        (loop (- n 1) (cons x xs)))))

(define (any? pred? xs)
  (cond ((null? xs) #f)
        ((pred? (car xs)) #t)
        (else (any? pred? (cdr xs)))))
```

Liang's dissertation described a program patgen for pre-computing the hyphenating and inhibiting rules, for English or any other language, given a hyphenating dictionary. This is harder than it looks, because the rules of hyphenation are arcane; consider, for instance, the difference between dem-on-stra-tion and de-mon-stra-tive (Liang resolves that particular problem by inhibiting the first hyphen in both words). Using patgen and a dictionary of fifty-thousand words (including inflected forms such as plurals and past participles formed by adding -s or -ed) with hyphenation points marked, Liang created the following list of 4447 patterns for TeX 82:

```
